```

Filter the data so that we use only listings for at most 6 people. From now on use this

```
listings_clean_filtered <- listings_clean %>%
filter(accommodates <= 6)</pre>
```

We also create a variable review_scores_rating_standardized with the standardized review score. This helps with the interpretation.

We still want to understand what prices depend on. We start with a simple model where we regress the log of the price on the standardized rating.

```
model1 <- lm(log(price) ~ review_scores_rating_standardized, data = listings_clean_filtered)
summary(model1)</pre>
```

```

That says that for a place that has a rating that is one standard deviation higher we can expect to pay a price that is 2.3 percent higher.

However, we also recall that earlier, we have already found out that the price is highly correlated with how many people can stay in an apartment (we found a coefficient of 0.21 in a regression of log price on 'accommodates'). So maybe that plays a role, too.

To find out, we carry out a multiple regression where we regress the log of the price on both the standardized rating and how many people can stay in it.

```
model2 <- lm(log(price) ~ review_scores_rating_standardized + accommodates, data = listings_clean_filter
summary(model2)</pre>

```

This now shows that the predicted price increases even more when the standardized rating increases by one unit, about 4.6 percent. We also see that if one additional person can stay in a place, then we can expect a price that is about 21 percent higher per night (this is similar to what we found in the Chapter 2 analysis before when we regressed the log price on 'accommodates').

To explain why the coefficient on review_scores_rating_standardized changes, we regress accommodates on review_scores_rating_standardized.

```
model3 <- lm(accommodates ~ review_scores_rating_standardized, data = listings_clean_filtered)
summary(model3)</pre>

This shows that places with a better rating, on average, accommodate less people.

In the lecture, we have learned that from the results in model2 and model3, we can reconstruct what we found in model1.

In model1, we look at the change in the predicted price when review_scores_rating_standardized changes by one unit (and there are no other variables in the model). In model3, we see that when review_scores_rating_standardized changes by one unit, then accommodates is predicted to change by -0.10587 units. But we know from model2 that when accommodates changes by one unit, we predict the log price to be higher by 0.21285 units when we hold the rating fixed (ceteris paribus).

So, we can go from model2 to model1 by saying that the predicted change in the log price when the rating changes by one standard deviation is the ceteris paribus effect of a change in review_scores_rating_standardized', 0.04554, plus how much we predictaccommodates to change whenreview_scores_rating_standardized changes by one unit, -0.10587, times the ceteris paribus effect of accommodates', 0.21285.

Here is some R code that does this calculation:

```
# Extract coefficients from model3 and model2
coef_rating_model2 <- coef(model2)["review_scores_rating_standardized"]
coef_accommodates_model2 <- coef(model2)["accommodates"]
coef_rating_model3 <- coef(model3)["review_scores_rating_standardized"]

# Calculate the desired value
result <- coef_rating_model2 + coef_rating_model3*coef_accommodates_model2

# Print the result
round(result,5)</pre>
```

```
## review_scores_rating_standardized
## 0.02301
```

This is the coefficient on review_scores_rating_standardized in model1.

Finally, we also make use of data on some neighborhood characteristics. These neighborhood characteristics were generated by chatGPT and are on a scale from 0 to 10. I've merged them with the web-scraped Airbnb data when I read in the data set. See build code for details.

Let's first look at some summary statistics.

```
# Calculate means and standard deviations for the four variables
summary_stats <- listings_clean_filtered %>%
summarise(
    Centrality_Mean = mean(Centrality, na.rm = TRUE),
```

```
Centrality_SD = sd(Centrality, na.rm = TRUE),
    Quietness_Mean = mean(Quietness, na.rm = TRUE),
    Quietness_SD = sd(Quietness, na.rm = TRUE),
    Coolness_Mean = mean(Coolness, na.rm = TRUE),
    Coolness_SD = sd(Coolness, na.rm = TRUE),
   Fanciness_Mean = mean(Fanciness, na.rm = TRUE),
    Fanciness_SD = sd(Fanciness, na.rm = TRUE)
  )
# Reshape to have one column for means and another for standard deviations
summary_stats_tidy <- data.frame(</pre>
  Variable = c("Centrality", "Quietness", "Coolness", "Fanciness"),
  Mean = c(summary_stats$Centrality_Mean, summary_stats$Quietness_Mean, summary_stats$Coolness_Mean, su
  SD = c(summary_stats$Centrality_SD, summary_stats$Quietness_SD, summary_stats$Coolness_SD, summary_st
# Display the table

                                                 0.04406
                                                           1.950 0.05186 .
## Quietness
                                      0.12896
                                                 0.04451
                                                           2.897 0.00397 **
## Coolness
                                      0.09606
                                                 0.07834 1.226 0.22079
## Fanciness
                                     -0.14765
                                                 0.05382 -2.744 0.00634 **
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
## Residual standard error: 0.3834 on 414 degrees of freedom
## Multiple R-squared: 0.3494, Adjusted R-squared:
```

```
## F-statistic: 37.05 on 6 and 414 DF, p-value: < 2.2e-16
```

This shows that prices are predicted to be higher when chatGPT rates the neighborhood more central, more quiet, more cool, and less fancy. This calls for more analysis.

As a first step, let's look at the list that has the highest value of Fanciness:

```
# Get the top 10 unique neighborhoods with the highest Fanciness values
top_neighborhoods_unique <- listings_clean_filtered %>%
    distinct(neighbourhood_cleansed, .keep_all = TRUE) %>%
    arrange(desc(Fanciness)) %>%
    select(neighbourhood_cleansed, Fanciness) %>%
    head(10)

# Print the list
top_neighborhoods_unique
```

##		neighbourhood_cleansed	Fanciness
##	1	Kop van Zuid	9
##	2	Kralingen Oost	9
##	3	Dijkzigt	8
##	4	Blijdorp	7
##	5	Katendrecht	7
##	6	Stadsdriehoek	7
##	7	Delfshaven	6
##	8	Liskwartier	6
##	9	Middelland	6
##	10	Noordereiland	6

At this point, it's unclear why Fanciness should lead to lower predicted prices. Feel free to do some analysis and let me know if you find out what could explain this!
